DEVELOPMENT

TIPS

We build [apps of all shapes and sizes](#) here at Savvy Apps, and one element is that they communicate with servers. Very few apps operate without some sort of Internet connectivity, meaning they interact with a backend, web services, or APIs. These APIs can be provided by Google, Amazon, Facebook, or comparable third parties, but they also could be APIs that are developed internally.

web services or APIs for apps specifically. In our experience, we've found guidelines on how to build better APIs for mobile apps [saves time and energy](#), reduces development and reduces headcount.

We wrote this guide to outline the best practices for building RESTful APIs for mobile apps and share our experiences.

108 Shares

Helpful API specifically for mobile apps and it's been very helpful for our customers as they work to properly build and maintain their mobile applications.

-
- Use a well-known architecture.
 - Make the server do the heavy lifting so mobile clients don't have to.
 - Version your API so it handles requests coming in from new and legacy clients.
 - Account for offline usage and usage across devices.
 - Prioritize performance and scalability when picking where to host your API.
 - Use standard security protocols and well-vetted authentication/authorization mechanisms.
 - Build three backend environments: development, staging, and production.
 - Let your data decide the type of database you use.
 - Construct API URL endpoints so that it's very clear what that resource represents.
 - For requests, let the client send full objects, and the server use them as-is.
 - Utilize UTC for dates/times, and let the client figure out how to display them.
 - Remember that GET and PUT requests need to be idempotent.

What to Know Before Using This RESTful API

REST is by far the most commonly-used style for designing APIs, especially in the mobile world. There are also particular subsets of REST, like [OData](#), that further reduce the amount of data that needs to be transmitted between your apps and the server. While those situations may be better suited for your particular needs, we're going to keep the conversation broad and general.

it works and, more importantly, how new services should be built onto it.

In this guide, we'll also be discussing some rules for your API too. In most cases, the

How Are Backends for Mobile Apps Different

Before we dive into the hosting, security, architecture, and other considerations for your RESTful API, let's examine what makes building an API for mobile a bit different from other systems. These mobile-specific concerns are essential to making sure your API is prepared to work efficiently with a mobile app and the expectations of its users.

HTTPS, Not HTTP

The internet was built on HTTP, but mobile platforms enforce HTTPS requiring modern encryption and trusted signed certificates. A mobile backend needs to have a certificate for every endpoint. Your development, staging, and production environments will all be using the same type of signed certificates. This will save you headache when you're ready to go live.

Server Does Most of the Work

To save on network data costs a lot of mobile clients do as little work as possible.

- [Concluding Note](#)

Server Issues Can Kill an App

You can also expect any errors a mobile user experiences to be broadcasted like a megaphone. Tech users these days have little patience when something goes wrong, especially mobile app users. There's no bigger stage for issues to play out than in App Store and Google Play app reviews. If something goes wrong, the developer needs to respond with user-friendly error messages or error codes the client can understand and, hopefully, help fix the issue. Even a single error can cause a 1-star rating. Positive reviews are critically linked to the success of an app. Too many negative reviews caused by server issues will stop new downloads for your app.

Versioning is More Important

With mobile app users updating their apps (or not) at different frequencies, versioning becomes more important than other, more controlled environments.

Considerations for Setting Up Your App's RESTful API

Now that we've looked at what sets mobile apart from other systems, we're ready to dive into planning your RESTful API. These tips address common concerns for mobile app development, including security, dealing with multiple devices, dealing with security, creating the backend architecture, choosing data storage options, using the right tools, and supporting multiple platforms.

Hosting the Server

Choosing the location to host your server is a big decision. If you don't have the resources or capacity to host your own bare-metal server, there are plenty of cloud-hosting options available.

evaluating services for where to host your server include:

- How does the service scale? (horizontally across multiple machines) or vertically (adding more power to one machine)
- How will the cost increase?
- Are there any migration environments (development, testing, production) available?
- What features are already included? (SSL/TLS, geo-location, energy from trying to reach a user's location, etc.)
- What steps does the service take to ensure data integrity, back ups, uptime monitoring, and failover?
- How easy can the data be accessed by mobile devices?

108 Shares

- [How Are Backends for Mobile Apps Different?](#)
- [Considerations for Setting Up Your App's RESTful API](#)
- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

Protecting the Data

Depending on your needs, you have a wide array of authentication mechanisms available to you. Any hosted service you choose should already include easy integration with SSL/TLS and the ability to use trusted CA certificates. HTTP Basic Authentication is the easiest to implement, but also the least secure. OAuth2 is widely accepted as a secure, standard way of authenticating users. There are plenty of libraries available for OAuth2 and even for phone number authentication you could use as well. Do not try to write your own authentication! There is no need to reinvent the wheel here when you can use existing protocols and libraries that have already been vetted by many others or even standardized on the server side. Protecting each API endpoint behind authentication requires a bit of work, but it is the norm. Don't allow free passes on a resource unless necessary for further development.

Sensitive data should be protected. This is a given, but security is a specific concern for mobile projects. Encrypt your user's sensitive data. Encryption may not be necessary for every project, but it should always be considered. Don't store your passwords in plain text. Please hash them. Not only should you hash passwords, but using random salts for each password is even better.

Planning the Architecture

As we already discussed, you're hopefully planning on building not one

[backend environments](#): develo

environment is where frequent

velopers. Data here can be

Otherwise, irreproducible slow downs, hang ups, and bugs may occur if
can be a nightmare to track down in development.

Making Database and Storage Decisions

No matter what type of database you use, it's worth noting that entity ID
randomly generated UUIDs, not sequential. This helps secure resources
much harder to guess. When it comes to storing your data, you might be
traditional relational database like MySQL or MariaDB. Or maybe you pr
of a noSQL document database like MongoDB. Or perhaps you prefer th
hybrid approach that something like PostgreSQL can offer with both rel
storage support. Which database your project should use is really going

Skip to a Section

- [What to Know Before Using This RESTful API Guide](#)
- [How Are Backends for Mobile Apps Different?](#)
- [Considerations for Setting Up Your App's RESTful API](#)
- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

MySQL/MariaDB

- Well established, stable and reliable
- Lots of libraries, frameworks and tools
- Data is rigid, well structured
- Scaling requires a lot of effort

108
Shares

MongoDB

- No tables, no formal schema
- Easier to scale than SQL
- Easy ramp up and iteration
- Easier to shoot yourself in the foot

greSQL

- Support and popularity is growing rapidly
- Built around giving more features and tools for DB admins
- Flexible enough to mix relational data with model-independent data

Cloud document storage

- A cheap solution could be something like using Amazon S3 Bucket to store sets of whole documents

Finding the Right Tools

You're going to need the right tools to get the job done. Whether it's communication between project teams, current team members, or future team members, the onboarding process for your project, communication is key to success of the project. During development, make sure you're using a clear dev-tracking system so that all your teammates have access. We're fans of [Pivotal Tracker](#) and [Trello](#), but a lot of other tools work.

writing the code to log in a user in an iOS app will really want to know what the authentication API is ready to consume. They may even have a discussion about the priorities of the server developer, blocking the iOS app from programmatic access to the API, not only what's currently being

the core principles of REST is stateless, which makes our API endpoints black boxes, ripe for testing. New data comes in, successful message contains newly persisted data changes are easily verifiable in the database. Requested expected data response comes out. [The testing framework to use](#) will contain the language you're writing the backend server logic in. No matter how they should be well-maintained and run with 100% passing rate before

During development, your testing suite may prove sufficient documentation for developers to review how the system works. Eventually you'll need to write in English, how the system you built actually works. I know this is the least of most of us, but it is critical for the success of a project in the long term. It is only as good as the effort you put into it. Fortunately, these days there are tools out there that can do a lot of the work for you. One of our favorite tools is [Postman](#). Not only is it useful for exploring or testing an API, but it generates all the requests, responses, and handles error codes and stores reference later. You can literally build your documentation as you build a suite for your new API.

- [Concluding Note](#)

Supporting Multiple Platforms

If you're building an API for a mobile app to consume, chances are good you'll want to support other platforms in the future. The general rule of thumb for building a RESTful API is to make the client as dumb and thin as possible, while keeping all the filtering, number crunching, data aggregating, and consolidation on the server. This leverages the more powerful hardware of the server and tries to keep the client from having to do too much work while fetching and showing the data to the user as quickly as possible.

This is important because when you're building your app on iOS, Android, and Windows Phone, you don't want to rewrite complicated filtering and parsing logic three times. For this reason, you'll want to allow robust sorting and filtering options, so the client only fetches what it needs. For example, don't return everything in a collection to the client app to sort through the data to find what it was looking for. Use pagination or lists of data to avoid overwhelming both the client and the user and all the servers.

those can be useful while reading logs and debugging in the future.

How to Execute Your RESTful API

Now that we've discussed how to actually design your API in a RESTful way, let's move on to executing it. We'll start by looking at how to handle URL paths, requests and responses in a RESTful API.

108 Shares

Handling URL Paths

In the rest of this guide, we're

going to look at how to handle URL paths. For example, some of your resources might be a book, a book club, an author, or a library location. The client would want access to all of those resources via their respective endpoints. So we could construct some endpoints mapping to:

```
GET      /books
POST     /books
GET      /books/{bookId}
PUT      /books/{bookId}
PATCH    /books/{bookId}
DELETE   /books/{bookId}
GET      /books/{bookId}/authors
GET      /bookClubs/book
GET      /users/{userId}
GET      /users/{userId}/favoriteBooks
```

Skip to a Section

- [What to Know Before Using This RESTful API Guide](#)
- [How Are Backends for Mobile Apps Different?](#)
- [Considerations for Setting Up Your App's RESTful API](#)
- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

Notice the pattern emerging. We hope to construct our API URL endpoint in a way that makes it very clear what that resource contains. Now let's talk about the two main components of RESTful API design: nouns and verbs. The actions GET, POST, PUT, PATCH, DELETE tell us what action to perform on the resource. The verb tells us what action to perform on the resource. The noun tells us what resource we're acting on. For example, if you wanted to add a new book to a library, you would use the POST method on the '/books' endpoint. If you wanted to update a book's information, you would use the PATCH method on the '/books/{bookId}' endpoint. If you wanted to delete a book from the library, you would use the DELETE method on the '/books/{bookId}' endpoint. The path itself tells you the nouns, which are the resources that will be acted upon. It's important to make this distinction here, because otherwise you could end up with URLs like '/books/1234567890' or '/books/1234567890/authors'. These URLs are not descriptive enough and can lead to confusion and errors. By using nouns and verbs in a RESTful way, we can create URLs that are both descriptive and easy to understand.

Now take a look at these (bad) endpoints:

/getBooks
/createNewBook
/checkOutBook/{bookId}
/returnBook/{bookId}

108 IdBookToFavorites
Shares IdNewMemberToBookClub
ChangeBookClubMeetingTime
ChangeBookClubMeetingLocation
RemoveBookClubMember

may glean more about what you're going to have to add to your source. Doing so will lead to f

to keep your API concise and modular. You're not only creating an right now, but you also need to think about how additional features or c into the API.

To improve your API's robustness, just let the requests drive the server's may seem like a silly statement, because of course a client will make a request. The server's job is to send a response. If the server is dictating what, how, and when to fetch or change data, then that means that every time they want to perform a feature, the client developers are going to have to wait for changes to be made. The server is allowed to refuse requests. That's what error messages are for. By using your endpoints with nouns and reacting to the data in the request, you'll end up with an API that will require less maintenance over time as you allow clients to c

Now, just because we're using nouns to drive the URLs, doesn't mean our URLs have to be the same as our data model objects. The URL should include model objects where appropriate, but we want to make these paths easy to read and intuitive. For example, resource / favoriteBooks probably will just return the same objects as / books, but it provides the clarification of what type of books we're going to get back. This is

Skip to a Section

- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

data and presenting it to the user.

This leads directly into how to handle filtering, sorting, pagination, and retrieving from the server. Again,

108 Shares From as possible here, without

le filtering, sorting, pagination, or our API endpoint quantity

to perform more complicated queries. Every parameters, we open up

sent to the users as they see fit. In alphabetical order, but tomorrow

useful to end users. Or maybe they want to let end users choose how

libraries sorted as a configurable setting. The client can do all of that without

work on the server side, which is what we want.

Here are some examples of handling these URL parameters for our library

```
GET /libraries?sortBy=name&isCurrentlyOpen=true&pageCount=10
GET /books?queryTitle=Sherlock+Holmes&queryAuthor=Arthur+Conan+Doyle
GET /bookClubs?genre=mystery
```

API versioning is another feature we should implement to achieve the right balance between functionality and compatibility, especially important for mobile apps. Mobile developers don't always have the luxury of forcing software updates for all end users, so our API is going to have to support both old and new requests. We'll do this by routing requests with a version number. Some people will argue that this version number should go in the URL path, and some prefer it to be placed in the request header. We prefer it to be in the URL path for ease of use, but that's up to you and your team to discuss. We treat versioned resources as separate resources, and that's why we think they deserve a unique path rather than

Skip to a Section

- [Considerations for Setting Up Your App's RESTful API](#)
- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

GET /v1/books
GET /v2/books

Another important guideline to follow is to organize related resources cascading from the root. This is shareable and intuitive for the user. If you're designing your API, consider how the client will interact with it. It's good to ask yourself questions like:

108 Shares

Skip to a Section

- [What to Know Before Using This RESTful API Guide](#)
- [How Are Backends for Mobile Apps Different?](#)

- [Concluding Note](#)

- Does a user need to log in to see this resource, or is it public?
- Does a user need to choose a library or city before viewing book details if the book is not attached to a particular location?
- What actions does the UI allow when viewing the details of a particular book? How can we design the API to allow the client to best perform those actions?

Rules for Requests and Responses

So we've laid out how we'll construct our API endpoints, now let's talk about how to communicate effectively within each of those endpoints. Let's start with handling a request, don't force the client to only send one or two fields. If a client wants to send full objects if they wish, while the server just uses the fields it needs. If a client sends only a few fields, don't assume the missing fields are null. Field names should be stated explicitly in both requests and responses. This prevents the client from having to guess if the data really is null or just not included. Take a look at the example below:

```
{  
  "author": "Arthur Conan Doyle"  
  "publicationYear": "1890"  
}
```

While this is not a complete book object, it contains important information. Here the URL is /books/1, as told by the URL. The fields author and publication year. Only these fields are relevant to the book object.

Details like the book's genre or price are not important for this request. The title of the book should be included in the response. Partial object requests require attention to the Content-Type and Accept headers in the request. The Content-Type header should remain application/json for most requests, but if you need to support other types of resources like files, images, or audio, you should place to do so (not in the URL!). Other types of resources like files, images, or audio should have their content type set and respected here as well.

Skip to a Section

- [What to Know Before Using This RESTful API Guide](#)
- [How Are Backends for Mobile Apps Different?](#)
- [Considerations for Setting Up Your App's RESTful API](#)
- [How to Execute Your RESTful API for Mobile Apps](#)
- [Concluding Note](#)

After handling the request, we need to send a response. Things might not always go as planned, and the client might expect something different than what the client expected and an error will need to be returned. Or maybe the request was processed successfully and simply doesn't require any data returned back to the client. In both cases, everything went exactly as expected. This is where the response HTTP status code comes into play.

Be deliberate with what status code is returned, with 200, 201, and 204 for successful responses, and 4XX codes for errors. You can bet the clients will be paying attention to these status codes, so we need to be careful with what we send back with our responses. While the client expects a 200 OK response though, we need to remain consistent. We should not be mixing up the key names between "snake_case" and "camelCase". The norm is camelCase, but an argument can be made for snake_case being more legible. Whatever you choose, use it everywhere.

about a book's ISBN. Pick one and use that key everywhere you need to

When sending responses that contain multiple objects, return them as an object versus an array. If the client needs to handle multiple objects, put it in an array and return it the way you did with the single object.

108 Shares Client for every programming language, there's a library designed to parse special cases on

flip side of this advice is doing it the wrong way. It's important to remember that just because it provides value, doesn't mean it's always the right choice. As a follow up, don't include fields that aren't requested. For example, we want the data mode to be "minimal" so that clients can choose what they want to receive. Wrapping in extra fields that aren't part of the requested object will just add unnecessary overhead.

Below are some examples of what **not** to put in your responses:

Don't wrap data with useless envelopes.

```
GET /authors?genre=mystery

{
  "data": [
    { "authorName": "Arthur Conan Doyle",
      ...
    }
  ]
}
```

Don't return a single object when the client should expect a collection.

```
GET /authors?genre=mystery

{
  "authorName": "Arthur Conan Doyle",
  ...
}
```

- [Concluding Note](#)

When dealing with dates and times, we return them in ISO 8601 format with U

ay format, or determine what precision the date-time data needs; typically, mobile apps will figure out how best to display the date and time to the user.

Aside from reading a request and creating or finding its response, the server is going to need some programmed logic to best execute each request. We must keep in mind when writing this logic that GET and PUT requests need to be idempotent, meaning that no matter how many times a client might call GET /books on our server, the results will remain unchanged. We should avoid doing anything “extra” or behind the scenes that the client might not expect. Whatever logic or indirect actions the server needs to perform in response to a request needs to be communicated and documented to a developer.

Concluding Note

Hopefully, this guide has been insightful. When designing and creating a RESTful API, we focus on placing resources in a modular, explorable, and extendible way, while communicating our decisions and priorities effectively. Constant collaboration between the developers working on the client apps and backend also ensures that [redundant code is avoided](#) and [continual progress is achieved](#). The less time we spend guess-
